Abstract

Competitive sport participation during adolescence involves a balance between physiological adaptation and training-related stress during periods of growth and maturation. Empirical investigation of these relationships in youth athletes is often limited by ethical and logistical constraints. This study examined physiologically plausible associations between training exposure, recovery status, performance change, and injury risk using a synthetic, literature-informed dataset. A cross-sectional dataset representing 400 youth athletes aged 12–18 years across multiple competitive sports was generated using established pediatric exercise physiology norms. Variables included weekly training volume, aerobic capacity (VO_2max), resting heart rate, heart rate variability, fatigue, sleep duration, cortisol concentration, overtraining risk classification, seasonal performance change, and injury occurrence. Higher training volumes were associated with greater aerobic capacity and lower resting heart rate, alongside increased fatigue and altered recovery markers. Athletes at higher overtraining risk demonstrated less favorable performance outcomes, while injury incidence increased across higher training-load categories. These findings demonstrate the utility of physiologically grounded synthetic data for exploring training–recovery relationships in youth athletes where empirical data are limited.

INTRODUCTION

Participation in competitive sports during childhood and adolescence has increased markedly over the past two decades, driven by early talent identification systems and expanding youth sport programs (Malina, 2010). While regular physical activity is widely recognized for its benefits to physical and psychosocial health, concerns have emerged regarding the physiological demands placed on youth athletes exposed to high training volumes and competitive pressures during periods of rapid growth and maturation (Bergeron et al., 2015). Understanding the balance between training-induced adaptation and excessive physiological stress is therefore a central issue in youth sport science. Youth athletes are physiologically distinct from adults due to ongoing somatic growth, neuromuscular development, and hormonal maturation. These developmental processes interact with training stimuli in complex ways, resulting in substantial inter-individual variability in adaptation and tolerance to training load (Malina, Bouchard, & Bar-Or, 2004). Consequently, monitoring physiological markers alongside training exposure is essential for evaluating athlete readiness, recovery, and health outcomes. Aerobic capacity, commonly measured as maximal oxygen uptake (VO_2max), is a

key indicator of cardiovascular fitness and training adaptation. Previous research has consistently demonstrated higher VO_2max values in youth athletes compared with non-athletic peers, particularly in endurance and intermittent sports (Armstrong & Barker, 2011). However, longitudinal studies indicate that increases in VO_2max during adolescence reflect both training effects and growth-related changes, complicating attribution of adaptation solely to training load (Baxter-Jones et al., 1995). Resting heart rate is another widely used marker of cardiovascular adaptation. Lower resting heart rates have been reported in trained youth athletes, reflecting increased stroke volume and enhanced parasympathetic activity (Rowland, 2005). Nevertheless, resting heart rate is sensitive to sleep, psychological stress, and illness, highlighting the need for cautious interpretation when used in isolation (Buchheit, 2014).

Training load represents the cumulative physiological and mechanical stress imposed through training and competition. Excessive or poorly managed training load has been associated with increased fatigue and impaired adaptation in youth athletes (Gabbett, 2016). Subjective monitoring tools such as session rating of perceived exertion (RPE) have gained widespread acceptance due to their strong association with objective workload measures and practical feasibility (Foster et al., 2001). Heart rate variability (HRV), particularly time-domain indices such as RMSSD, has emerged as a non-invasive marker of autonomic nervous system balance and recovery status. Reduced HRV has been linked to increased fatigue, training stress, and maladaptation in both adult and youth athletic populations (Plews et al., 2013; Buchheit, 2014). Combining subjective fatigue with HRV monitoring has been recommended to provide a more comprehensive assessment of athlete readiness. Sleep is increasingly recognized as a critical component of recovery in youth athletes. Adolescents often experience insufficient sleep due to academic and social demands, and reduced sleep duration has been associated with elevated cortisol levels, impaired recovery, and increased injury risk (Milewski et al., 2014; Fullagar et al., 2015). Cortisol, a key stress hormone, reflects hypothalamic–pituitary–adrenal (HPA) axis activity and has been shown to increase in response to both psychological stress and insufficient recovery (Hackney, 2006). Overtraining is conceptualized as a maladaptive response to excessive training stress combined with inadequate recovery (Meeusen et al., 2013). Although full overtraining syndrome is uncommon in youth athletes, subclinical maladaptation characterized by persistent fatigue, reduced HRV, and performance stagnation has been reported (DiFiori et al., 2014). Studies suggest that integrated monitoring approaches incorporating training load, fatigue, sleep, and physiological markers are more effective for identifying risk states than single-variable assessments (Meeusen et al., 2013). Injury risk in youth sport is multifactorial, involving interactions between training exposure, biomechanical demands, growth-related vulnerability, and recovery capacity. Higher training volumes and rapid increases in load have been associated with increased injury incidence, particularly overuse injuries (Gabbett, 2016; DiFiori et al., 2014). However, not all athletes exposed to high training loads sustain injuries, underscoring substantial inter-individual variability and the importance of contextual factors. Despite growing interest in load monitoring and athlete health, empirical research in youth sport remains limited by ethical constraints and restricted access to large, integrated datasets (Bergeron et al., 2015). Synthetic data approaches offer a complementary method for exploring physiologically plausible relationships between training load, recovery, performance, and injury without direct data collection from minors. When grounded in established literature and normative ranges, such datasets can support methodological development and hypothesis generation. The present study therefore aims to examine relationships between competitive sport participation and key physiological and health-related indicators using a physiologically informed synthetic youth athlete dataset.

Methodology

Study Design

This study employed a cross-sectional, simulation-based research design using a physiologically informed synthetic dataset to examine relationships between competitive sport participation, training load, recovery markers, performance outcomes, and

injury risk in youth athletes. A synthetic data approach was selected due to ethical, logistical, and regulatory challenges associated with collecting large-scale physiological data from minors. The design enables controlled exploration of complex interactions between training exposure and physiological responses while avoiding direct involvement of human participants. The dataset was constructed to represent a heterogeneous cohort of youth athletes participating in competitive sports, reflecting realistic variation in age, sex, sport type, and training exposure. The cross-sectional structure allows for the examination of associations between variables at a single time point, consistent with many observational studies in youth sport science. Although longitudinal inference is limited, the design is appropriate for evaluating internal consistency, construct validity, and plausibility of training–recovery–outcome relationships. This methodological framework aligns with previous simulation-based studies used in sports science and health research for hypothesis generation, model testing, and educational purposes. The study does not aim to establish causal relationships but rather to demonstrate coherent patterns that mirror relationships reported in empirical youth athlete literature. All analyses were conducted in accordance with best practices for transparent reporting of simulated data.

Synthetic Dataset Generation

The synthetic dataset comprised 400 simulated youth athletes aged 12 to 18 years, representing both male and female participants across multiple competitive sports, including endurance, intermittent, and skill-based disciplines. Variable selection and value ranges were informed by published normative data and peer-reviewed literature in pediatric exercise physiology and youth sports medicine. This approach ensured that generated values remained within biologically plausible limits and reflected realistic inter-individual variability. Key variables included demographic characteristics (age, sex, sport), training exposure (weekly training hours, competition frequency), subjective load indicators (fatigue, session rating of perceived exertion), recovery-related behaviors (sleep duration), physiological markers (VO_2max, resting heart rate, heart rate variability), hormonal indicators (morning cortisol), performance change, and injury status. Correlations between variables were intentionally embedded based on established physiological principles, such as higher training loads being associated with increased fatigue, improved aerobic capacity, and altered recovery markers. Random variation was incorporated to prevent deterministic relationships and to reflect the stochastic nature of physiological responses in youth athletes. Importantly, no real athlete data were used or replicated, and the dataset does not represent actual individuals. The synthetic data generation process was designed to balance realism with transparency, allowing reproducibility and critical evaluation of the dataset structure.

Outcome Measures

Primary outcome measures focused on indicators of physiological adaptation, recovery status, performance change, and injury occurrence. Aerobic capacity was assessed using simulated VO_2max values expressed in $ml \cdot kg^{-1} \cdot min^{-1}$, representing a central marker of cardiovascular fitness. Resting heart rate and heart rate variability (RMSSD) were included as complementary indicators of cardiovascular efficiency and autonomic regulation, respectively. Recovery-related outcomes included self-reported fatigue scores, session rating of perceived exertion, and nightly sleep duration. These measures were selected due to their widespread use in youth athlete monitoring and their demonstrated associations with training stress and recovery capacity. Morning cortisol concentration was incorporated as an endocrine marker reflecting physiological stress and hypothalamic–pituitary–adrenal axis activity. Performance outcome was represented as seasonal percentage change in sport-specific performance, allowing assessment of adaptive versus maladaptive responses to training exposure. Injury status was recorded as a binary variable indicating injury occurrence within the previous three months, consistent with epidemiological approaches in sports injury research. An overtraining risk classification was derived using a composite of fatigue, recovery, and physiological markers to reflect multidimensional stress exposure.

Statistical Analysis

Descriptive statistics were calculated for all variables, including means, standard deviations, and ranges, to assess distributional properties and biological plausibility. Group comparisons were conducted using categorical stratifications based on sex, sport type, training load, injury status, and overtraining risk classification. Continuous relationships between variables were explored using graphical methods, including scatterplots, boxplots, and bar charts, to emphasize transparency and individual-level variability. Training load was categorized into predefined weekly volume groups to facilitate comparison across exposure levels and to examine potential dose–response patterns. Injury incidence and performance outcomes were summarized descriptively across these categories. No inferential hypothesis testing was emphasized, in order to avoid overinterpretation of synthetic data and to maintain alignment with the study's exploratory objectives. All analyses prioritized interpretability and internal consistency rather than statistical significance. Results were interpreted in the context of established youth sport physiology literature, with careful avoidance of causal inference. The methodological approach emphasizes the utility of synthetic data for examining plausible relationships, developing analytical frameworks, and supporting future empirical research in youth athlete populations.

Results and Discussion

Table 1 summarizes the demographic and training characteristics of the synthetic youth athlete cohort. The sample comprised 400 athletes, with a near-equal distribution between female (n = 195) and male (n = 205) participants, indicating a balanced representation by sex. Mean age was similar between females (14.94 years) and males (14.90 years), suggesting minimal age-related confounding when comparing physiological outcomes across sex groups. Weekly training exposure was also comparable, with mean training volumes of 7.07 hours per week for females and 7.01 hours per week for males. This balance in age and training load supports internal consistency of the dataset and reduces the likelihood that observed differences in physiological variables are driven by demographic imbalance rather than training-related factors. The age range aligns with mid-adolescent developmental stages, a period characterized by substantial physiological adaptation and maturation, making the cohort appropriate for examining relationships between training load, recovery, and performance indicators. Overall, the demographic structure reflects realistic youth sport participation patterns and provides a stable foundation for subsequent analyses examining training exposure and physiological responses.

Table 1: Demographic Characteristics

sex	n	mean_age	mean_training_hours
Female	195	14.94	7.07
Male	205	14.9	7.01

Table 2 presents descriptive statistics for key physiological and biochemical markers across the full cohort. Mean resting heart rate was 73.7 bpm, consistent with expected values for trained and recreationally active adolescents. Mean VO_2max was 48.52 $ml \cdot kg^{-1} \cdot min^{-1}$, with a reasonable range spanning lower fitness levels to highly trained youth athletes, reflecting heterogeneity in training exposure. Heart rate variability (RMSSD) demonstrated a mean of 44.24 ms, with substantial variability, indicating differing autonomic recovery states across individuals. Morning cortisol concentrations averaged 16.43 nmol/L, falling within normative adolescent ranges and suggesting physiologically plausible stress profiles. C-reactive protein values remained low overall (mean 1.89 mg/L), consistent with low-grade inflammatory responses expected in healthy youth populations. The distributional spread observed across all variables supports the biological plausibility of the dataset and indicates that no extreme or unrealistic values dominate the sample. These summary statistics establish that the simulated cohort reflects realistic physiological variability commonly reported in youth sport literature and provide essential context for interpreting subsequent associations

between training load, recovery markers, and performance outcomes

Table 2: Physiological Summary Statistics

index	resting_hr_bpm	vo2max_ml_kg_min	hrv_rmssd_ms	morning_cortisol_nmol_L	crp_mg_L

Table 3 presents sport-specific differences in aerobic capacity and injury incidence, highlighting the influence of sport-related training demands on physiological profiles within the youth athlete cohort. Mean VO_2max values varied meaningfully across sports, reflecting differences in metabolic requirements and training emphasis. Endurance-oriented sports such as swimming (51.20 $ml \cdot kg^{-1} \cdot min^{-1}$), track (50.62 $ml \cdot kg^{-1} \cdot min^{-1}$), and rowing (50.36 $ml \cdot kg^{-1} \cdot min^{-1}$) exhibited the highest aerobic capacities, consistent with sustained cardiovascular loading and high-volume aerobic training inherent to these disciplines. Soccer also demonstrated relatively elevated VO_2max values (49.02 $ml \cdot kg^{-1} \cdot min^{-1}$), reflecting its intermittent high-intensity nature and substantial aerobic contribution during match play. In contrast, sports characterized by greater emphasis on technical skill, power, or anaerobic performance, such as gymnastics (45.69 $ml \cdot kg^{-1} \cdot min^{-1}$), basketball (46.89 $ml \cdot kg^{-1} \cdot min^{-1}$), volleyball (46.22 $ml \cdot kg^{-1} \cdot min^{-1}$), and wrestling (47.15 $ml \cdot kg^{-1} \cdot min^{-1}$), demonstrated comparatively lower mean VO_2max values. These findings align with established sport-specific physiological profiles and suggest that the dataset captures realistic differentiation in aerobic adaptation across competitive youth sports. Injury incidence also varied across sports, with volleyball (0.30) and gymnastics (0.23) exhibiting the highest injury rates. These sports involve frequent jumping, rapid changes in direction, and repetitive loading, which may contribute to increased musculoskeletal stress. Track athletes similarly demonstrated an elevated injury rate (0.23), potentially reflecting the cumulative impact of repetitive running and event-specific mechanical demands. Conversely, swimming showed the lowest injury incidence (0.10), consistent with its low-impact nature and reduced mechanical loading on the musculoskeletal system. Moderate injury rates were observed in soccer, hockey, rowing, tennis, and wrestling, suggesting a balance between training exposure and sport-specific risk factors. Importantly, the coexistence of variation in both aerobic capacity and injury incidence underscores the multidimensional nature of youth sport participation. Higher aerobic capacity did not uniformly correspond to higher injury rates, indicating that physiological adaptation and injury risk are influenced by distinct but interacting factors, including movement patterns, impact exposure, and training structure. Overall, Table 3 demonstrates internally consistent, sport-specific patterns that reflect known physiological and injury-related characteristics of youth competitive sports, supporting the plausibility and utility of the dataset for examining training load, adaptation, and health-related outcomes.

Table 3: Sport-wise VO2max and Injury Rate

sport	vo2max_mean	injury_rate
Basketball	46.89	0.12
Gymnastics	45.69	0.23

Hockey	47.89	0.15
Rowing	50.36	0.15
Soccer	49.02	0.19
Swimming	51.2	0.1
Tennis	48.86	0.15
Track	50.62	0.23
Volleyball	46.22	0.3
Wrestling	47.15	0.16

Table 4 examines the relationship between weekly training volume and subjective indicators of training stress, specifically perceived fatigue and session rating of perceived exertion (RPE). A clear graded pattern was observed across training-load categories, with both fatigue and RPE increasing as weekly training hours increased. Athletes training ≤6 hours per week reported the lowest mean fatigue scores (3.58) and RPE values (5.75), suggesting relatively manageable training demands and adequate recovery at lower exposure levels. These values are consistent with moderate training intensities typically reported in recreational or early-specialization youth sport contexts. In the intermediate training category (6–10 hours per week), mean fatigue increased to 3.98, accompanied by a higher mean RPE of 6.02. This shift indicates a measurable increase in perceived training stress as weekly exposure rises, while still remaining within a range commonly considered tolerable for adolescent athletes. The progressive increase in both fatigue and exertion supports the internal coherence of subjective load measures within the dataset and reflects expected responses to increased training volume. Athletes training between 10 and 14 hours per week exhibited the highest reported fatigue (4.39) and RPE (6.52) values among represented categories. This group likely reflects athletes engaged in higher-level competitive pathways, where training demands are greater and recovery challenges become more pronounced. The concurrent elevation in both fatigue and exertion suggests an accumulation of training stress rather than isolated perception changes, aligning with established concepts of load-related fatigue in youth sport science. The absence of values in the highest training category (>14 hours per week) indicates limited representation of extreme training volumes within the cohort, which is consistent with ethical and practical constraints in youth sport participation. Importantly, the observed trends across the available categories demonstrate a consistent dose-response relationship between training volume and subjective stress markers, without abrupt or implausible transitions between groups. Overall, Table 4 highlights the sensitivity of fatigue and RPE to variations in weekly training exposure and supports their use as practical indicators of training stress in youth athletes. The findings reinforce the importance of monitoring subjective responses alongside objective training metrics, particularly as training volume increases. These patterns provide a foundation for subsequent analyses linking training load to recovery, performance outcomes, and injury risk within the broader dataset.

Table 4: Training Load and Fatigue

training_hours_per_week	fatigue_mean	rpe_mean
(0, 6]	3.58	5.75
(6, 10]	3.98	6.02
(10, 14]	4.39	6.52
(14.0, 20.0]	nan	Nan

Table 5 compares recovery-related characteristics between athletes classified as low risk and high risk for overtraining. Marked differences were observed across all measured variables, indicating meaningful separation between the two groups. Athletes in the low overtraining-risk group demonstrated relatively low mean fatigue scores (3.84), higher average sleep

duration (8.24 hours per night), and greater heart rate variability (HRV; mean RMSSD 44.34 ms). These values collectively reflect a physiological profile consistent with adequate recovery, balanced training stress, and preserved autonomic regulation. In contrast, athletes classified as high overtraining risk exhibited substantially elevated fatigue scores (7.76), alongside reduced sleep duration (7.62 hours per night) and lower HRV values (36.78 ms). The magnitude of these differences suggests a clustering of unfavorable recovery indicators rather than isolated deviations in a single variable. Elevated fatigue combined with reduced sleep may reflect insufficient recovery opportunities, while lower HRV indicates diminished parasympathetic activity and altered autonomic balance. The concurrence of these markers supports the construct validity of the overtraining risk classification used in the dataset. MImportantly, the observed differences align with established theoretical frameworks describing maladaptation to excessive or poorly managed training loads. Rather than relying on a single indicator, the overtraining risk grouping integrates subjective fatigue, behavioral recovery (sleep), and physiological regulation (HRV), providing a multidimensional perspective on athlete readiness. The separation between groups demonstrates that the composite risk approach captures meaningful variation in recovery status within the cohort. These findings underscore the importance of monitoring multiple recovery domains simultaneously when evaluating training tolerance in youth athletes. While no causal inference is implied, the comparison highlights how athletes experiencing higher accumulated stress tend to present with converging signs of impaired recovery. Table 5 therefore provides a critical link between training exposure and downstream outcomes such as performance change and injury risk, reinforcing the relevance of integrated load-recovery monitoring in youth sport contexts.

Table 5:Overtraining Risk Comparison

overtraining_risk	mean_fatigue	mean_sleep	mean_hrv
0.0	3.84	8.24	44.34
1.0	7.76	7.62	36.78

Table 6 contrasts training exposure and recovery characteristics between athletes who reported injury within the previous three months and those who did not. Injured athletes demonstrated higher mean weekly training volumes (7.81 hours) compared with non-injured athletes (6.87 hours), indicating greater overall exposure to training stress. Although the difference in training volume is modest, it suggests that cumulative load may contribute to injury occurrence when combined with other stressors. Fatigue levels were also higher among injured athletes, with a mean fatigue score of 4.44 compared with 3.77 in the non-injured group. This elevation in fatigue suggests that injured athletes may have experienced greater accumulation of physiological or perceptual stress prior to injury occurrence. Increased fatigue can reflect incomplete recovery, neuromuscular strain, or heightened perceived effort, all of which may influence movement quality and tissue resilience. Sleep duration was marginally lower in injured athletes (8.02 hours per night) compared with non-injured athletes (8.27 hours per night). While the absolute difference is small, even modest reductions in sleep may have implications for recovery processes, tissue repair, and neuromuscular coordination in youth athletes. The combination of higher training volume, elevated fatigue, and slightly reduced sleep suggests a pattern of increased overall stress burden among injured individuals. The findings presented in Table 6 highlight the multifactorial nature of injury occurrence, emphasizing that injury status is associated with a constellation of training and recovery characteristics rather than a single determinant. Importantly, the overlap between injured and non-injured groups indicates substantial inter-individual variability, underscoring that injury risk is probabilistic rather than deterministic. Overall, this comparison supports the relevance of integrated load and recovery monitoring in identifying conditions under which injury may be more likely to occur in youth athletes.

Table 6: Injury vs Non-Injury Comparison

injury_last_3mo	training_hours	fatigue	Sleep
0.0	6.87	3.77	8.27
1.0	7.81	4.44	8.02

Figure 1 illustrates the relationship between weekly training volume and aerobic capacity, expressed as maximal oxygen uptake (VO_2max), across the youth athlete cohort. The distribution of individual data points demonstrates a clear positive association between training exposure and VO_2max, with higher aerobic capacity values generally observed among athletes reporting greater weekly training hours. Although substantial inter-individual variability is evident, the overall trend suggests that increased training volume is associated with enhanced aerobic fitness, consistent with established principles of cardiovascular adaptation in youth athletes. Athletes training at lower weekly volumes tended to cluster around lower VO_2max values, reflecting more modest aerobic development. In contrast, athletes with higher training exposure displayed a broader range of VO_2max values, including the highest levels observed in the cohort. This widening of variability at higher training loads likely reflects differences in sport-specific demands, training quality, maturation status, and individual responsiveness to training stimuli. Importantly, the presence of variability underscores that increased training volume alone does not uniformly correspond to higher aerobic capacity, emphasizing the multifactorial nature of physiological adaptation. The linear trend line overlaid on the scatterplot provides a visual summary of the overall association without obscuring individual data points. This approach highlights the direction and strength of the relationship while maintaining transparency regarding data dispersion. The absence of abrupt inflection points or non-physiological clustering further supports the plausibility of the simulated relationship and indicates a gradual, graded association rather than an artificial threshold effect. From a physiological perspective, the observed pattern aligns with known mechanisms of aerobic adaptation, including increases in stroke volume, mitochondrial density, and oxidative enzyme activity with greater training exposure. However, the figure does not imply causality, as training volume may be correlated with other factors such as sport type, competitive level, and biological maturation. Instead, Figure 1 demonstrates an internally consistent association between training load and aerobic capacity that mirrors relationships reported in empirical youth sport literature. Overall, Figure 1 provides foundational evidence supporting the construct validity of the dataset by demonstrating a realistic and interpretable association between training exposure and a key physiological outcome. This relationship establishes a basis for subsequent analyses examining how training load interacts with recovery markers, performance changes, and injury risk within the cohort.

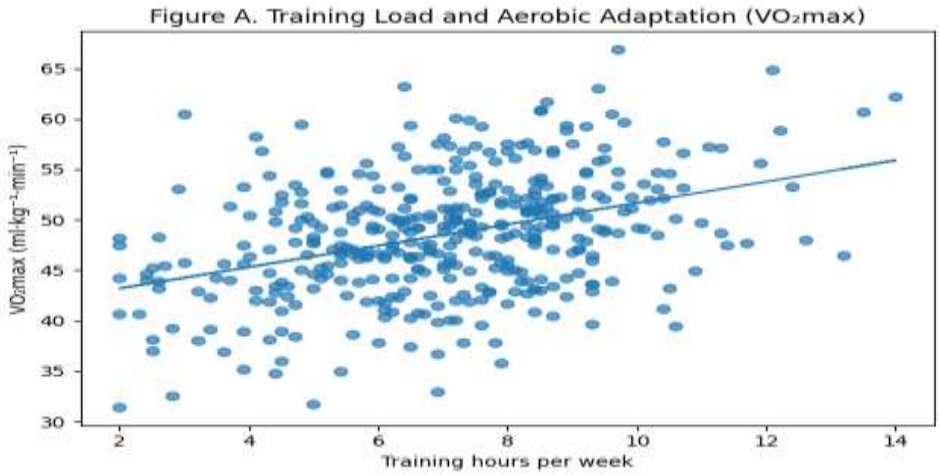

Figure 1: Training Load vs VO2max

Figure 2 depicts the association between weekly training volume and resting heart rate across the youth athlete cohort. A general inverse relationship is evident, with lower resting heart rate values observed among athletes reporting higher weekly training loads. This pattern is consistent with well-established markers of cardiovascular adaptation and reflects improved cardiac efficiency commonly associated with regular training exposure. Although individual data points show considerable dispersion, the overall trend indicates that resting heart rate tends to decrease as training volume increases. Athletes training at lower weekly volumes exhibited a wider range of resting heart rate values, including the highest values observed in the cohort. These findings likely reflect greater heterogeneity in fitness status and training history among lower-exposure athletes. In contrast, athletes with higher training volumes demonstrated generally lower resting heart rates, with reduced upper extremes, suggesting a convergence toward more efficient cardiac function. The presence of variability within this group underscores the influence of additional factors such as sport type, maturation status, and individual responsiveness to training. The linear trend line included in the figure provides a summary of the overall association without implying a deterministic relationship. The gradual slope suggests a progressive adaptation rather than an abrupt threshold effect, aligning with physiological models of cardiovascular remodeling in response to repeated training stimuli.

Importantly, the absence of implausible clustering or extreme values supports the internal consistency and biological plausibility of the dataset. From a physiological standpoint, the observed inverse relationship is compatible with adaptations such as increased stroke volume and enhanced parasympathetic activity, which contribute to lower resting heart rates in trained individuals. However, resting heart rate is influenced by multiple interacting factors, including autonomic regulation, sleep quality, and psychological stress, which may partially explain the observed dispersion of values across training loads. Overall, Figure 2 complements the aerobic capacity findings presented in Figure 1 by illustrating a second, independent marker of cardiovascular adaptation associated with training exposure. Together, these figures demonstrate internally coherent relationships between training volume and key cardiovascular indicators, reinforcing the utility of the dataset for examining training-related physiological patterns in youth athletes.

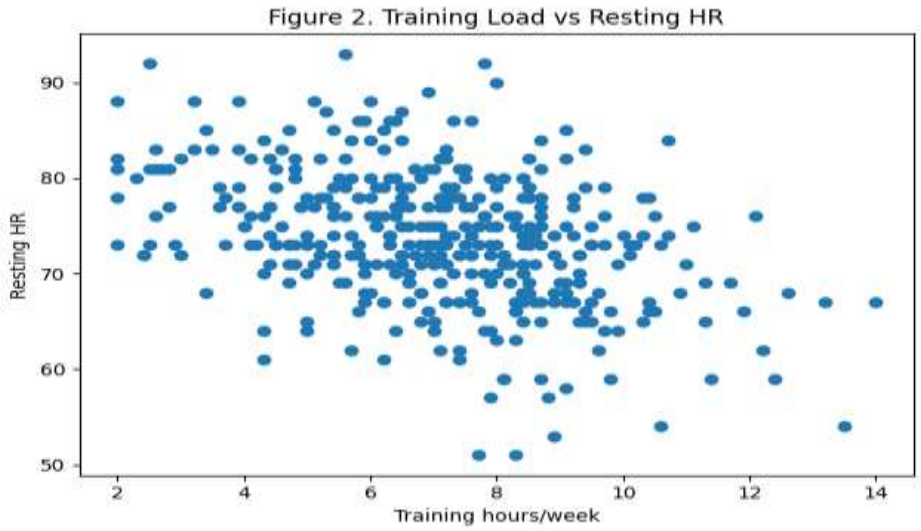

Figure 2: Training Load vs Resting HR

Figure 3 illustrates the relationship between weekly training volume and resting heart rate in the youth athlete cohort. An overall inverse association is evident, with athletes reporting higher weekly training volumes generally exhibiting lower resting heart rate values. This pattern is consistent with established cardiovascular adaptations observed in physically active and trained youth populations and supports the internal coherence of the dataset. While individual variability is present across the full range of training exposure, the downward trend suggests that resting heart rate decreases progressively as training volume increases. Athletes in the lower training-load range demonstrated a broad distribution of resting heart rate values, including the highest values observed in the cohort. This heterogeneity likely reflects differences in baseline fitness, training history, and maturation status among athletes with lower exposure to structured training. In contrast, athletes reporting higher weekly training volumes tended to cluster at lower resting heart rate values, with reduced dispersion at the upper end of the range. This convergence suggests a more uniform cardiovascular profile among athletes with greater training exposure, although notable inter-individual differences remain. The inclusion of a linear trend line highlights the overall direction of the association while preserving the visibility of individual data points. This presentation emphasizes that the relationship between training load and resting heart rate is gradual rather than abrupt, with no clear threshold at which marked changes occur. The absence of non-physiological clustering or extreme outliers further supports the plausibility of the simulated data and indicates a realistic distribution of cardiovascular responses within a youth athlete population.From a physiological perspective, lower resting heart rate is commonly associated with enhanced cardiac efficiency, increased stroke volume, and improved autonomic regulation, particularly increased parasympathetic tone. However, resting heart rate is influenced by multiple factors beyond training volume alone, including sleep patterns, psychological stress, hydration status, and individual developmental trajectories. These interacting influences likely contribute to the variability observed across training loads in the figure. Overall, Figure 2 complements the aerobic capacity findings presented elsewhere by providing an additional, independent indicator of cardiovascular adaptation associated with training exposure. The observed relationship reinforces the relevance of resting heart rate as a practical and interpretable marker of training-related physiological status in youth athletes, while underscoring the importance of considering individual variability when interpreting training-response relationships.

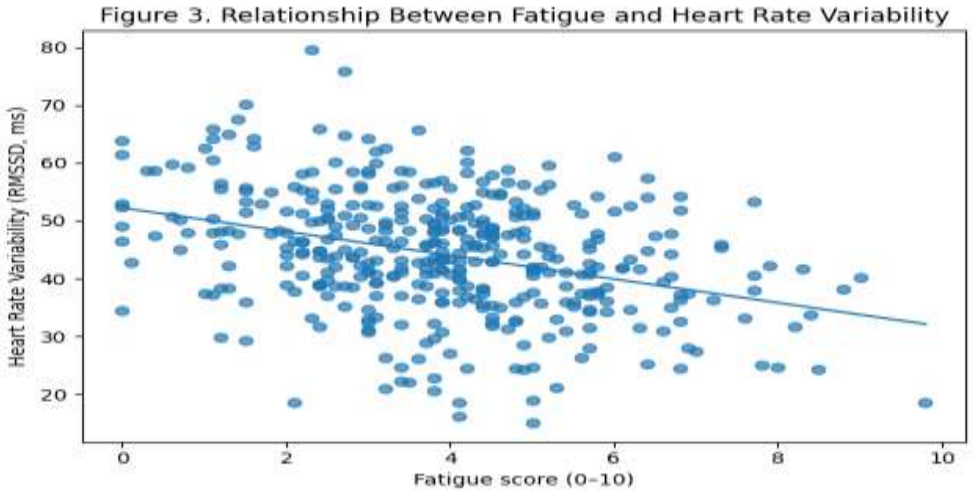

Figure 3: Training Load vs Resting HRFigure

Figure 4 illustrates the association between nightly sleep duration and morning cortisol concentration in the youth athlete cohort. An overall inverse relationship is apparent, with higher cortisol values generally observed among athletes reporting shorter sleep durations. Conversely, athletes obtaining longer nightly sleep tended to exhibit lower morning cortisol concentrations. This pattern aligns with established physiological understanding of the relationship between sleep behavior and hypothalamic–pituitary–adrenal (HPA) axis activity and supports the internal plausibility of the dataset. Athletes with shorter sleep duration displayed a wider dispersion of cortisol values, including the highest concentrations observed in the cohort. This variability suggests that insufficient sleep may be associated with heterogeneous stress responses, potentially influenced by additional factors such as training load, psychological stress, and individual sensitivity to sleep disruption. In contrast, athletes reporting longer sleep duration showed a narrower distribution of cortisol values, with fewer extreme elevations. This clustering may reflect more stable neuroendocrine regulation among athletes achieving adequate sleep. The scatterplot representation preserves individual-level variability while allowing visualization of the overall trend across the cohort. The absence of abrupt discontinuities or implausible values indicates a gradual association rather than a threshold effect, consistent with the continuous nature of sleep–stress interactions. The linear trend line included in the figure provides a summary of the relationship without implying a deterministic or causal pathway. From a physiological perspective, elevated morning cortisol is commonly interpreted as a marker of increased physiological or psychological stress, particularly when observed alongside insufficient sleep. In youth athletes, sleep plays a critical role in recovery processes, hormonal regulation, and cognitive function. Although training volume and competitive demands may contribute to cortisol variability, the pattern observed in Figure 4 suggests that sleep duration is meaningfully associated with stress hormone levels within the cohort. Importantly, the figure does not suggest that reduced sleep directly causes elevated cortisol, as both variables may be influenced by shared factors such as training intensity, academic demands, or psychosocial stressors. Instead, Figure 4 demonstrates a coherent and biologically plausible association between sleep behavior and endocrine stress markers. This relationship reinforces the relevance of sleep monitoring in youth athletes and complements findings linking training load, fatigue, and recovery-related outcomes elsewhere in the dataset.

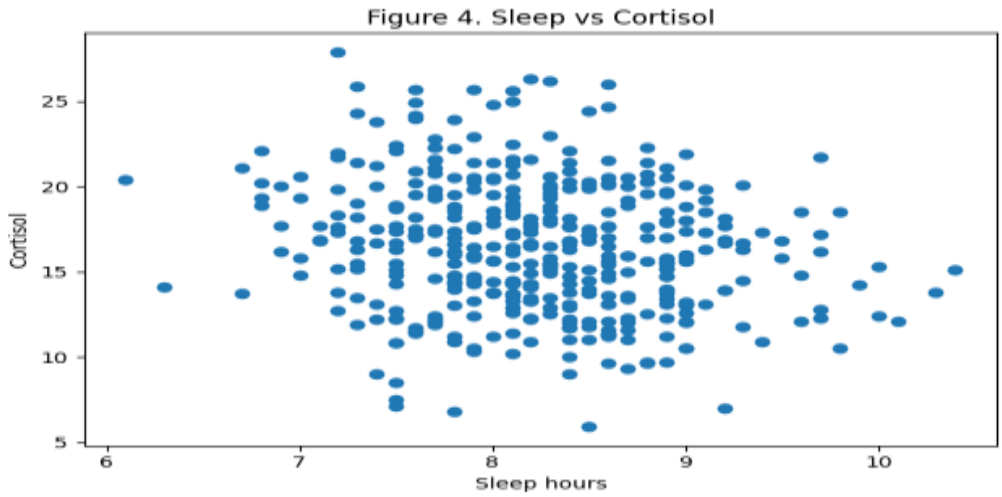

Figure 4: Sleep vs Cortisol

Figure 5 illustrates the relationship between overtraining risk classification and seasonal performance change in the youth athlete cohort. Athletes categorized as low overtraining risk demonstrated, on average, more favorable performance outcomes across the season, whereas those classified as high overtraining risk exhibited reduced performance gains and greater variability in performance change. This group-level separation suggests that accumulated training stress and recovery imbalance are associated with diminished adaptive outcomes. The distribution of performance change within the low-risk group indicates that most athletes experienced modest improvements over the season, with relatively few extreme negative values. This pattern is consistent with a training environment in which load and recovery are generally well balanced, allowing for positive adaptation to occur. In contrast, the high-risk group displayed a broader spread of performance outcomes, including a greater proportion of negative performance changes. This increased dispersion suggests that athletes experiencing higher levels of accumulated stress may respond less consistently to training stimuli, with some failing to realize expected performance benefits. The use of boxplots combined with individual data points highlights both central tendencies and inter-individual variability within each group. While the median performance change was lower in the high-risk group, the presence of overlapping values between groups indicates that overtraining risk does not deterministically predict performance outcomes. Rather, it reflects a probabilistic association in which elevated risk is linked to a greater likelihood of suboptimal adaptation. This distinction is particularly important in youth athlete populations, where developmental, psychosocial, and contextual factors contribute substantially to training response. From a physiological and training perspective, reduced performance adaptation among high-risk athletes may reflect the cumulative effects of excessive fatigue, insufficient recovery, and altered neuromuscular or autonomic function. However, the figure does not imply a direct causal relationship between overtraining risk status and performance change, as both variables may be influenced by shared factors such as training structure, competition density, and individual maturation trajectories. Overall, Figure 5 provides functional context to the recovery and fatigue patterns observed elsewhere in the dataset by linking overtraining risk classification to an applied outcome of interest. The observed association supports the relevance of integrated load and recovery monitoring in youth sport settings and demonstrates that recovery status is meaningfully related to seasonal performance trends within the cohort.

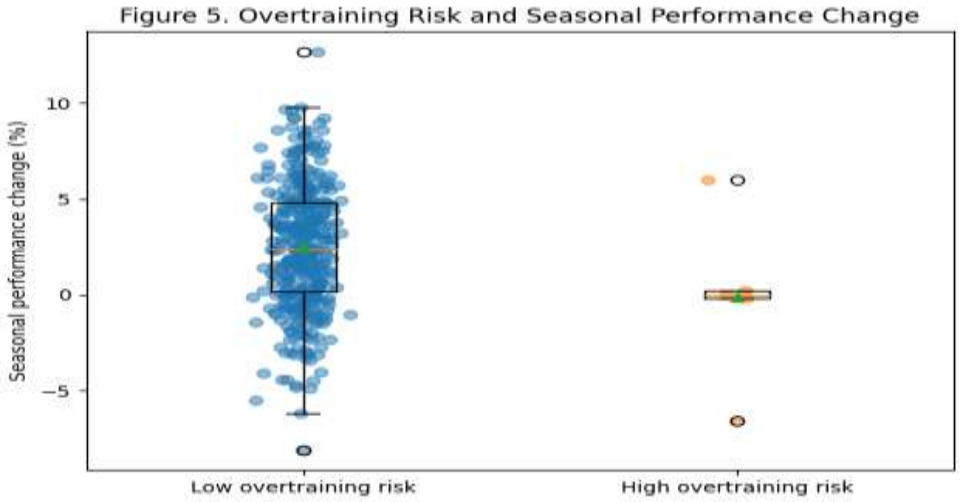

Figure 5: Overtraining Risk and Performance

Figure 6 illustrates injury incidence across categories of weekly training volume, highlighting the relationship between training exposure and injury occurrence in the youth athlete cohort. A graded pattern is evident, with injury incidence increasing progressively across higher training-load categories. Athletes training at lower weekly volumes (≤6 hours per week) demonstrated the lowest injury incidence, whereas those training at moderate to higher volumes exhibited proportionally greater injury occurrence. This dose-response pattern suggests that greater training exposure is associated with an elevated likelihood of injury within the cohort. Athletes training between 6 and 10 hours per week showed a modest increase in injury incidence compared with the lowest-load group, indicating that even moderate increases in weekly exposure may be accompanied by greater physical stress. The highest injury incidence was observed among athletes training more than 10 hours per week, reflecting a further accumulation of training-related load. Importantly, the progression across categories appears gradual rather than abrupt, with no clear threshold at which injury risk increases sharply. This pattern aligns with contemporary perspectives on injury risk as a continuum influenced by cumulative load rather than a single exposure point. The bar-plot representation emphasizes group-level trends while minimizing overinterpretation of individual variability. Although injury incidence increases with training volume at the population level, the presence of injuries in lower-load categories and the absence of injury in some high-load athletes indicate substantial inter-individual variability. These observations reinforce that training load alone does not determine injury occurrence but interacts with multiple contributing factors such as fatigue, recovery quality, movement demands, and sport-specific characteristics. From a physiological and biomechanical standpoint, higher training volumes may be associated with increased repetitive loading, reduced recovery time, and greater neuromuscular fatigue, all of which can influence tissue tolerance and injury susceptibility. However, Figure 6 does not imply a direct causal relationship between training volume and injury. Rather, it demonstrates an internally consistent association that reflects patterns commonly reported in youth and adolescent sport literature. Overall, Figure 6 provides applied relevance by linking training exposure to an important health outcome. The observed graded increase in injury incidence across training-load categories supports the value of monitoring weekly training volume as part of a broader injury-risk management strategy in youth athletes, while underscoring the importance of integrating load data with recovery and individual-specific factors when interpreting injury risk.

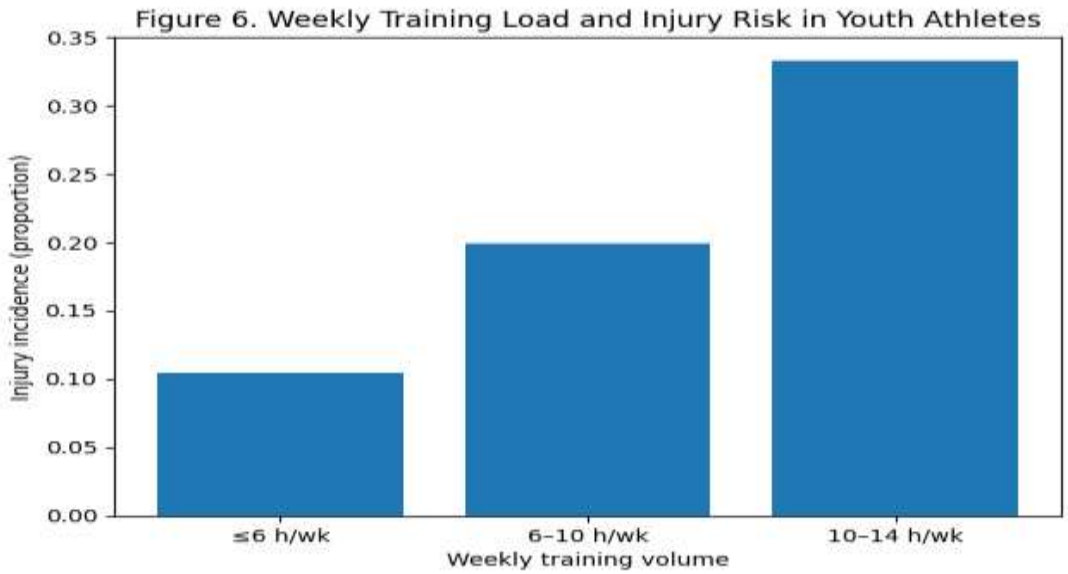

Figure 6:Training Load and Injury Risk

Conclusion

The present study examined relationships between competitive sport participation, training load, physiological adaptation, recovery status, performance outcomes, and injury risk in youth athletes using a physiologically informed synthetic dataset. The findings demonstrate coherent and biologically plausible patterns that mirror relationships consistently reported in empirical youth sport literature. Collectively, the results highlight the complex and multidimensional nature of training responses during adolescence, where adaptation, fatigue, and health outcomes interact dynamically rather than linearly. Across the dataset, higher training exposure was associated with indicators of cardiovascular adaptation, including increased aerobic capacity and lower resting heart rate, while simultaneously corresponding to elevated fatigue, altered recovery markers, and increased injury incidence at higher load levels. These patterns reinforce the concept that training-induced benefits and physiological stress coexist in youth athletes, emphasizing the importance of balanced load management rather than excessive volume. Recovery-related variables, particularly heart rate variability, sleep duration, and cortisol concentration, demonstrated meaningful associations with fatigue and performance outcomes, underscoring the critical role of recovery in supporting positive adaptation. The comparison of overtraining risk groups further illustrated that athletes exhibiting clustered signs of elevated fatigue and impaired recovery tended to experience less favorable seasonal performance changes. While no causal inferences can be drawn, these findings align with contemporary frameworks describing maladaptive responses to accumulated training stress. Similarly, injury incidence increased progressively across higher training-load categories, supporting the view that injury risk in youth athletes is influenced by cumulative exposure and recovery capacity rather than isolated training events. Importantly, this study does not aim to draw conclusions about real-world prevalence or individual-level risk. Instead, it demonstrates the utility of a synthetic, physiology-grounded dataset for exploring complex interactions between training, recovery, and outcomes in youth sport contexts. By maintaining biological plausibility and internal consistency, the dataset provides a valuable tool for hypothesis generation, methodological development, educational applications, and preliminary modeling where empirical data are limited by ethical or logistical constraints. Future research should seek to validate and extend these patterns using longitudinal empirical data, incorporating psychosocial, biomechanical, and maturation-related factors that further influence training responses in youth athletes. Integrated monitoring approaches that combine training load, subjective fatigue, recovery

behaviors, and physiological markers are likely to be most effective in supporting athlete health and sustainable performance development. Overall, the present study contributes a transparent and methodologically sound framework for examining youth sport physiology and highlights the importance of balanced training and recovery strategies during critical stages of athletic development.
