Abstract

Groundwater, the planet's largest accessible freshwater reserve, faces escalating depletion due to urbanization, agriculture (consuming ~70% of supplies), and climate change, with global demand projected to rise 20–30% by 2050. This review synthesizes advances in hydrogeological modeling for sustainable aquifer management, tracing the evolution from analytical to numerical and hybrid AI-integrated frameworks. Key governing equations, such as the 3D saturated flow model based on Darcy's Law and mass conservation, underpin simulations in tools like MODFLOW (finite-difference) and FEFLOW (finite-element), each suited to specific complexities (e.g., regional vs. multi-physics). Essential data inputs include hydraulic properties (conductivity, transmissivity), piezometric levels, and recharge/discharge patterns, while managed aquifer recharge (MAR) emerges as a critical intervention, enhanced by machine learning for site optimization and performance prediction. Challenges like seawater intrusion, land subsidence, and model uncertainty are addressed through socio-hydrogeological integration and participatory governance aligned with SDGs. Future directions emphasize coupled Earth system models and global intercomparisons (e.g., ISIMIP) to mitigate overexploitation and ensure resilience in interconnected human-water systems.

INTRODUCTION

1. The Imperative of Groundwater Sustainability in the Anthropocene

Groundwater represents Earth's largest non-frozen freshwater reservoir, serving as a critical buffer for water supply security in the face of escalating climatic and anthropogenic pressures (Zanini & Celico, 2025). As the global population continues to expand and urbanization accelerates, the reliance on subsurface resources has shifted from a supplemental source to a primary lifeline for domestic, agricultural, and industrial sectors (Brindha et al., 2019). Currently, agriculture alone consumes approximately 70% of the global water supply, with the remaining 30% divided between industrial and domestic use. Projections indicate that global water demand will increase by 20% to 30% by 2050, potentially reaching volumes of 5,500 to 6,000 cubic kilometers per year (Pattison & Cooke, 2024). This trajectory places immense stress on aquifer systems, many of which are already experiencing unprecedented rates of

depletion due to over-extraction and disrupted recharge patterns (Gantayat et al., 2025).

The management of these systems has historically been hindered by the "invisible" nature of groundwater, leading to a neglect of its dynamics in large-scale hydrological models and political agendas (Gleeson et al., 2020). However, the emergence of sophisticated hydrogeological modeling tools has provided a framework for visualizing and quantifying these subsurface processes, transitioning the field from a reactive discipline to a proactive science of sustainability (Basel et al., 2022). Sustainable management is no longer defined solely by the physical state of the aquifer but is increasingly viewed through the lens of groundwater-connected systems, which encompass the social, ecological, and economic feedback loops that interact with physical groundwater bodies (Huggins et al., 2023).

2. Conceptual Foundations and the Transition to Numerical Frameworks

The evolution of hydrogeological assessment is characterized by a significant progression from analytical models to high-fidelity numerical and hybrid approaches (Dai et al., 2025). In its early stages, the field relied on analytical models simplified mathematical representations of groundwater behavior that typically assumed homogeneity and constant properties in space and time (Wali et al., 2024). While these models provided fundamental conceptual clarity, they were often confined to localized flow systems and lacked the capacity to address the spatial complexity and heterogeneity inherent in real-world aquifer systems (Razavi et al., 2025).

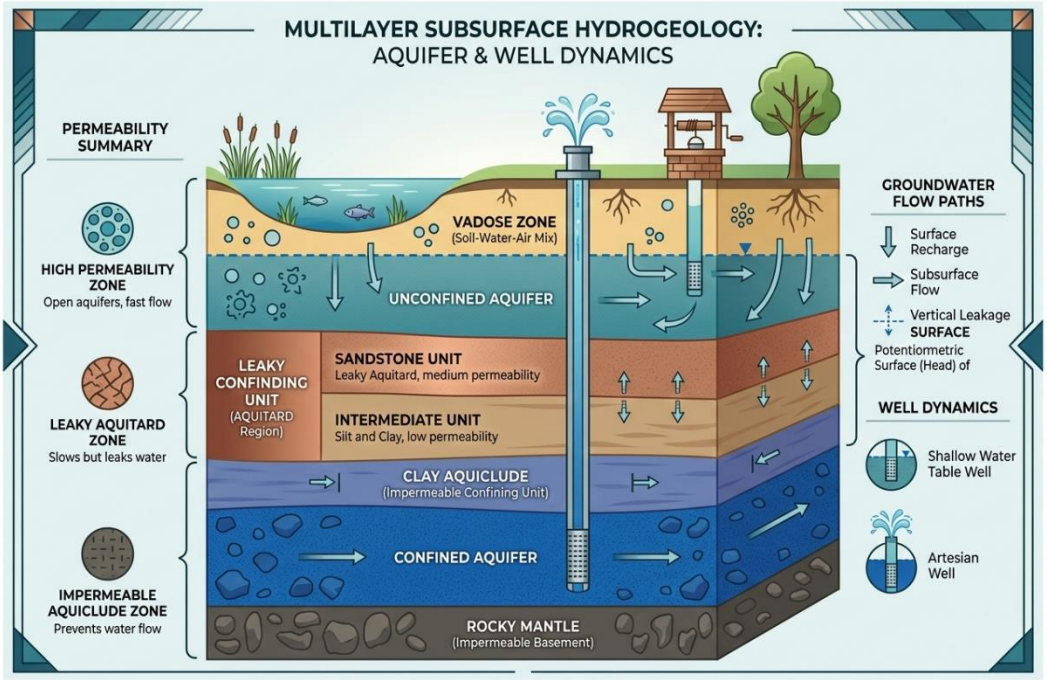

Figure 1. Conceptualization of Multi-Layered Aquifer Systems, Flow Paths, and Well Dynamics in Heterogeneous Subsurface Environments.

The shift toward numerical modeling was catalyzed by the need for greater precision in simulating complex flow and contaminant transport in heterogeneous subsurface environments. Numerical models discretize the aquifer into a grid or mesh, allowing for the representation of varying hydraulic properties and irregular boundary conditions (Regnier et al., 2022).

Table 1: Overview of Groundwater Modeling Paradigms

Modeling Paradigm	Characteristics	Analytical Basis	Primary Limitations
Analytical	Closed-form solutions, simplified geometry, homogeneous media.	Darcy's Law, Theis Equation.	Inability to capture spatial heterogeneity or irregular boundaries.
Numerical	Discretized domains (grids/meshes), handles anisotropy, 3D simulations.	Finite Difference, Finite Element methods.	High data requirements, computational intensity.
Hybrid/GeoAI	Integration of physical models with AI/ML and remote sensing.	Model-Data Fusion, Deep Learning.	Interpretability challenges, "black-box" perceptions.

3. Mathematical Governing Equations and Dimensional Complexity

At the core of any hydrogeological numerical model lies the governing equation for three-dimensional saturated flow in porous media. Derived from the principles of mass conservation and Darcy's Law, this equation describes how hydraulic head evolves over time in response to spatial variations in hydraulic conductivity and external stresses (Lee, 2024).

The standard form of the governing equation, written in simple text, is:

Ss · (dh/dt) = d/dx (Kxx · dh/dx) + d/dy (Kyy · dh/dy) + d/dz (Kzz · dh/dz) + W

In this expression:

- *h* represents the hydraulic head.
- *t* denotes time.
- *Kxx*, *Kyy*, and *Kzz* are the principal components of the hydraulic conductivity tensor in the x, y, and z directions, respectively.
- *Ss* is the specific storage of the porous medium.
- *W* is the volumetric flux per unit volume, representing sources and/or sinks of water (e.g., recharge or pumping).

Solving this partial differential equation requires the specification of appropriate initial and boundary conditions. Initial conditions define the distribution of hydraulic head at the beginning of the simulation, while boundary conditions describe the interactions between the modeled domain and its surrounding environment (O'Sullivan et al., 2022).

4. Comparative Analysis of Modeling Software: MODFLOW vs. FEFLOW

The choice of modeling software is a critical decision in hydrogeological projects, often dictated by the complexity of the geological setting and project objectives. MODFLOW and FEFLOW are the two most prominent platforms globally, each utilizing a distinct mathematical approach to solve the groundwater flow equations (Chang. 2025).

MODFLOW, developed by the U.S. Geological Survey (USGS), is a modular finite-difference groundwater model. It is the most widely used 3D groundwater flow software, primarily due to its open-source nature and acceptance by government agencies worldwide (Kumar, 2019).

FEFLOW (Finite Element subsurface FLOW system) utilizes the finite-element method, which offers superior flexibility in modeling complex geometry and coupled phenomena (Shah al., 2026).

Table 2: Comparison of MODFLOW and FEFLOW Software Platforms

Feature	MODFLOW	FEFLOW
Mathematical Method	Finite Difference (modular).	Finite Element.
Grid/Mesh Type	Structured (standard) or Unstructured (USG).	Unstructured, flexible mesh.
Primary Strength	Wide acceptance, approachable GUI, regional efficiency.	Geometric flexibility, coupled processes (heat/solute).
Ideal Application	Government reporting, regional management.	Complex watersheds, multi-physics research.
Usability	Moderate (experience-dependent).	High GUI integration (steeper learning curve).

5. Data Requirements for Robust Aquifer Simulation

The accuracy of a hydrogeological model is fundamentally limited by the data available for its construction and calibration. A robust simulation requires a comprehensive synthesis of both the physical and hydrological frameworks of the system (Borzì, 2025).

Hydrological data describes the dynamic behavior of water and includes:

- **Hydraulic Properties:** Hydraulic conductivity (K), transmissivity (T), and storativity (S) are typically determined through field-based techniques like pumping tests and geophysical surveys (Bai et al., 2018).
- **Piezometric Monitoring:** Time-series of groundwater levels are essential for setting initial conditions and for the calibration-validation process (Tamayo-Mas et al., 2018).
- **Recharge and Discharge Patterns:** Quantifying the rate and spatial distribution of water entering the aquifer is critical for sustainability planning (Manzoni et al., 2024).

6. Managed Aquifer Recharge (MAR) and Sustainable Yield

As natural recharge patterns are disrupted by climate change, Managed Aquifer Recharge (MAR) has emerged as a vital technology for replenishing groundwater through artificial means. MAR systems aim to improve water security by storing surplus water in subsurface aquifers during wet periods for use during droughts (Rozikulov et al., 2025).

The design and management of MAR projects are increasingly supported by machine learning (ML) methodologies. ML models are employed to predict MAR performance factors, optimize injection rates, and evaluate the suitability of potential recharge sites based on complex hydrogeological and climatic factors (Sheik et al., 2024).

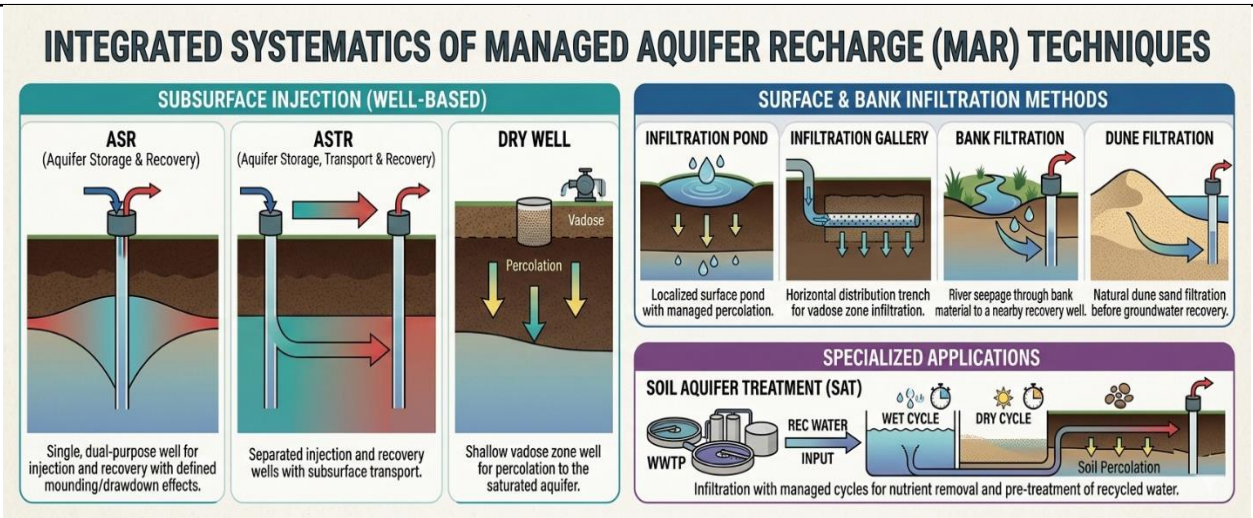

Figure 2. Categorization of Managed Aquifer Recharge (MAR) Methodologies: Subsurface Injection, Surface Infiltration, and Specialized Soil Aquifer Treatment (SAT).

7. Modeling Saltwater Intrusion and Coastal Vulnerability

Coastal aquifers provide freshwater for approximately 40% of the world's population, yet they are increasingly threatened by saltwater intrusion (SWI). Numerical modeling is an indispensable tool for managing these systems, particularly through variable-density flow codes (Perumal et al., 2024).

Table 3: Numerical Tools for Coastal Saltwater Intrusion

SWI Modeling Tool	Mathematical Approach	Specific Application
SEAWAT	Fully coupled variable-density flow and transport.	Detailed 3D interface dynamics, heat plumes.
SUTRA	Finite-element fluid-saturated porous media.	Complex 2D/3D density-dependent flow.
SWI2 (MODFLOW)	Reduced-order, vertically averaged density.	Rapid regional assessment, SLR scenarios.

8. Land Subsidence and Aquifer-System Compaction

A critical consequence of groundwater over-extraction is land subsidence the sinking of the ground surface due to the compaction of fine-grained interbeds within an aquifer system. Modeling land subsidence is essential for protecting infrastructure and managing regional water stress (Mohamed, 2025). A study integrating climate change scenarios (CMIP6) and water demand projections (SSPs) found that future subsidence is primarily driven by socio-economic factors (water demand) rather than direct climate change effects (Tabari et al., 2025).

9. The Rise of Artificial Intelligence and Machine Learning in Hydrogeology

The integration of Artificial Intelligence (AI) and Machine Learning (ML) into hydrogeological workflows represents a paradigm shift. ML algorithms are being deployed to manage the complexity and non-linearity of aquifer systems (Kuhaneswaran et al., 2025).

- **Predictive Monitoring:** ML models like Long Short-Term Memory (LSTM) networks have shown success in forecasting groundwater levels,

outperforming traditional conceptual models (Kumar, 2019).

- **Model-Data Fusion:** ML is used to quantify model uncertainty through techniques like Bayesian Model Averaging (Regnier et al., 2022).

10. Remote Sensing and GRACE Satellite Gravimetry

In many regions, remote sensing (RS) has emerged as a crucial tool for filling data gaps. The Gravity Recovery and Climate Experiment (GRACE) provides estimates of changes in Terrestrial Water Storage (TWS) through variations in the Earth's gravity field (Huggins et al., 2023). GRACE data assimilation (DA) into numerical models allows for a more accurate representation of climate-driven changes and anthropogenic influences, such as irrigation-induced depletion (Mahadeva & Sindhushree, 2025).

11. Socio-Hydrogeology and the Human Dimensions of Groundwater

Sustainable groundwater management is fundamentally a social challenge. Socio-hydrogeology seeks to understand the reciprocal interactions between human behavior and groundwater systems (Gleeson et al., 2020). Effective policy integration requires transitioning to "participatory governance," where hydrogeologists bridge technical simulation and social action. This framing supports the Sustainable Development Goals (SDGs), particularly SDG 6 (Clean Water and Sanitation) (Pattison & Cooke, 2024).

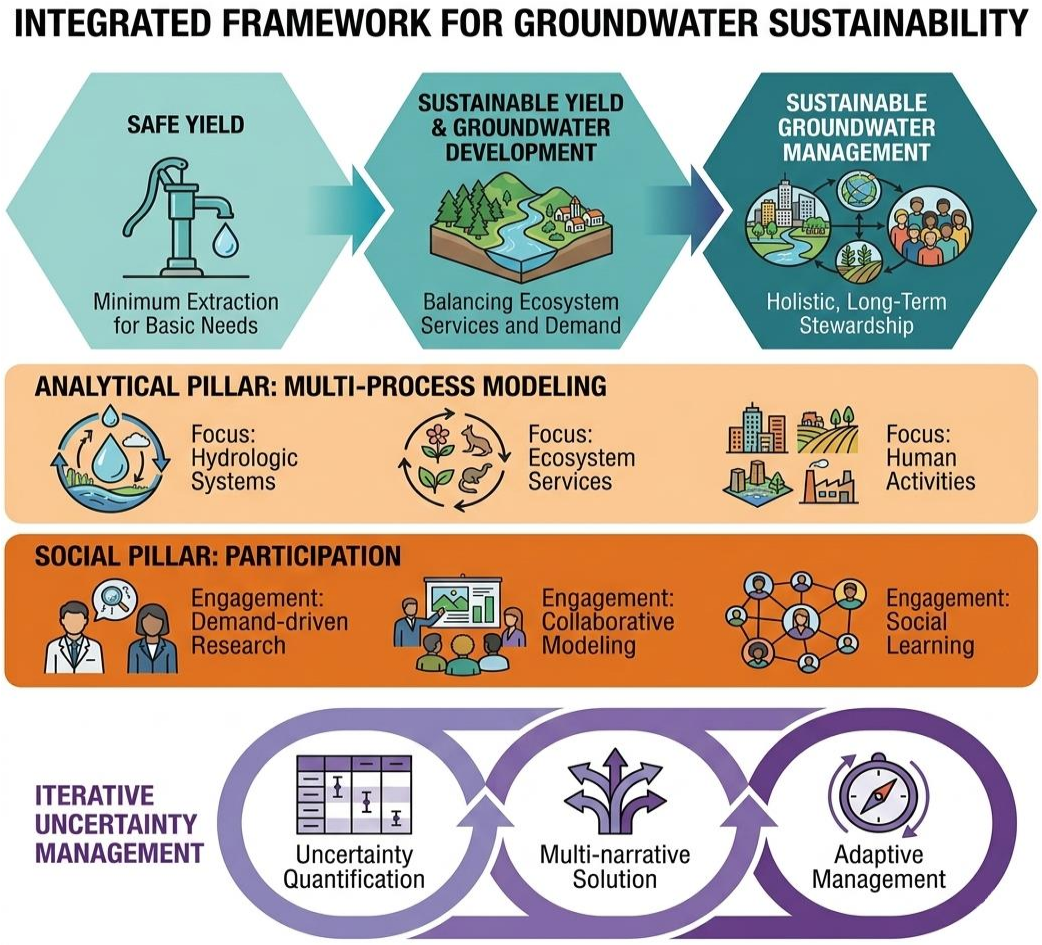

Figure 3. A Multi-Pillar Framework for Sustainable Groundwater Stewardship: Integrating Analytical Modeling, Social Participation, and Iterative Uncertainty Management.

12. Uncertainty, Calibration, and Methodological Limitations

Despite sophisticated models, significant uncertainties remain regarding data quality and poorly quantified human influences. Dynamic frameworks are increasingly preferred because they can account for the evolving nature of both climatic inputs and anthropogenic pressures (He et al., 2025). Coupled dynamic-spatial modeling has been used to forecast the evolution of groundwater vulnerability, showing how risk zones expand as urbanization and reduced recharge converge (McMillan et al., 2018).

13. Future Outlook: Toward Integrated Earth System Modeling

The future of hydrogeological modeling is moving toward "integrated" or "coupled" Earth system models that simulate the entire terrestrial water cycle from the atmosphere to deep aquifers (Gantayat et al., 2025). This includes global intercomparison projects like ISIMIP, which combine multiple models to reduce uncertainty in climate projections. Achieving sustainable groundwater management requires not only advanced numerical codes but also a commitment to data transparency and community engagement (Zanini & Celico, 2025).

Conclusion

Hydrogeological modeling has transformed from simplistic analytical tools to sophisticated numerical and AI-augmented platforms, enabling proactive sustainable management of aquifer systems amid escalating anthropogenic and climatic pressures. By integrating physical equations with high-resolution data on hydraulic properties, recharge dynamics, and human impacts, models like MODFLOW and FEFLOW provide essential insights for quantifying depletion risks, optimizing MAR schemes, and forecasting vulnerabilities such as seawater intrusion and subsidence. However, persistent uncertainties in data quality and social feedbacks underscore the need for socio-hydrogeological approaches that foster participatory governance and align with global sustainability goals (e.g., SDG 6). As demand surges toward 6,000 km³/year by 2050, the path forward lies in coupled Earth system simulations, enhanced data fusion, and interdisciplinary collaboration to safeguard groundwater as a resilient buffer for food security, ecosystems, and human well-being in an increasingly water-stressed world.2.4sExpert
